On gender gaps and self-fulfilling expectations: 
Theory, policies and some empirical evidence*

ABSTRACT

This paper develops a simple model of self-fulfilling expectations by firms and households that generates multiplicity of equilibria in both pay and time allocation between home and market work for ex-ante identical individuals, except for gender. Rather than relying on the existence of incentive problems in the labour market, as is common in the literature, multiplicity of equilibria arises from the role of statistical discrimination in firm’s decisions about the provision of specific training to workers. Firms’ beliefs about differences in spouses’ reactions to household shocks lead to symmetric (ungendered) and asymmetric (gendered) equilibria. We find that: (i) the ungendered equilibrium can become a unique equilibrium as the economy becomes more productive, regardless of the generosity of family aid policies, (ii) the ungendered equilibrium could yield higher welfare than the gendered one under some scenarios, and (iii) gender-neutral job subsidies are more effective that gender-targeted ones in removing the gendered equilibrium. Empirical evidence based on time use surveys for three European countries yields some support for these implications.

JEL Classification: J16 and J71.

Keywords: gender gaps, housework shares, multiple equilibria.

1. Introduction

There is an extensive literature that studies the joint determination of gender differentials in earnings and in the household division of labour.\(^1\) Most of these studies stem from Becker’s (1985, 1991) observation that a small initial comparative advantage of women in household production (e.g., in bearing and nurturing children) can lead to full specialization over time, due to learning-by-doing and the increasing marginal disutility of market work caused by housework. However, as pointed out by several authors (see, e.g., Albanesi and Olivetti, 2007), huge improvements in medical and household technologies (plus less need of physical strength in most jobs) have increasingly rendered this comparative advantage unimportant and yet sizeable gender differences persist in pay and in labour allocation in the household (see Bassanini and Saint Martin, 2008 for a recent review).

Several explanations that do not resort to genetic differences or explicit prejudice against women have been proposed in the literature to explain the persistence of gender gaps. They often rely upon incentive problems in the labour market which lead to self-fulfilling prophecies about differences in gender roles when initial comparative advantages are absent. The basic idea is that firms’ beliefs about women’s lower attachment to the labour market leads to earnings differentials in favour of men. Hence, since the expected opportunity cost is lower for women, they end up devoting more time to housework, validating in this way firms’ beliefs. For instance, Albanesi and Olivetti (2009) propose a model in which firms are subject to incentive compatible constraints due to their imperfect monitoring of effort (a moral hazard problem) and hours of housework (an adverse selection problem). As a result, they end up offering different types of labour contracts to men and women. Another related paper example is Lommerud and Vagstad (2007) who follow Lazear and Rosen’s (1990) model of job ladders in assuming that there are two types of jobs: fast track and slow track jobs. Firms need to pay a fixed investment cost in order to place workers in fast track jobs and effort is not perfectly observable. Hence, if women have been traditionally the gender exerting primary major responsibility at home and wages are non-contractible, they will predominantly follow a “mommy track” in equilibrium.

Our paper contributes to this literature in several ways. First, we propose an

alternative mechanism, based on statistical discrimination in the provision of training by firms to male and female workers, which also yields multiplicity of equilibria in the absence of moral hazard problems.\textsuperscript{2} While incentive problems - often used to derive additional predictions on the structure of wages to be confronted with the data – could be a useful modelling device, they can also be somewhat restrictive. For instance, as regards the difficulty of perfectly monitoring effort, wage gaps should be negligible for routine tasks performed by less-skilled employees for whom effort and output should be easily observable. Yet, substantial pay gaps still remain in these categories even when differences in observable characteristics and overall wage dispersion are controlled for (see, e.g., Blau and Kahn, 2000, Bassanini and Saint Martin, 2008, and de la Rica \textit{et al.} 2008). Regarding the substitutability of effort at housework and market work, one could likewise argue that, since several housework activities are akin to running a “small firm”, they may lead to better organizational skills improving female performance in marketplace work rather than being detrimental (see, e.g., Wolfers, 2006).

Specifically, statistical discrimination in our setup arises from firms’ different expectations about the allocation of time between husbands and wives, once they have received paid-for training, when their households face disutility shocks (e.g., unexpected need of housework or events that require parental leave, etc.). If wages are predetermined with respect to these shocks, these asymmetric beliefs will induce differences in the provision of training across genders. This will lead to differences in wages, which will also be taken as parametric when households decide upon the distribution of housework. Under some assumptions about the distribution of disutility shocks and the degree of diminishing returns to training, two types of equilibria exist: (i) an \textit{ungendered} equilibrium, with a fully egalitarian division of housework and equal pay, and (ii) a \textit{gendered} equilibrium, where one of the household’s members (typically men) higher wages than women and devote less time to housework.

In this fashion, we are able to generate some novel predictions about the relationship between the division of housework and gender wage gaps relative to the large strand of literature on this topic that relies upon incentive problems. For example,\textsuperscript{2}

\textsuperscript{2} Following the seminal work by Arrow and Phelps, there is a large literature on statistical discrimination leading to asymmetric treatment in equilibrium of \textit{ex ante} identical groups. In particular, our model deals with some of the issues raised before by Moro and Norman (2003, 2004), namely, the interaction between an informational externality and general equilibrium effects. However, whereas their cross-group externalities come from the marginal productivity of one group being affected by the size of another group in market work (say the ratio of black and white workers in a given occupation), ours relies upon household decisions on housework interacting with firms’ decision on training.
we find that, under plausible conditions and abstracting from the availability of more generous gender policies, the gendered equilibrium tends to vanish in economies with higher labour productivity levels (e.g., where training results in larger productivity gains). Further, regarding the role of policies in reducing gender gaps, we find that gender-neutral policies tend to be more effective than gender-based policies. In particular, we find that, in the case where an ungendered equilibrium prevails, job subsidies targeted at women can backfire by shifting the economy to an even more unequal equilibrium.3 Lastly, in contrast to most existing work (see, e.g., the discussion in Lommenrud and Vagstad, 2007), we find that welfare could be higher in the symmetric than in the asymmetric equilibrium. The reason why the converse result is often found in the literature is because an asymmetric equilibrium promotes some form of “efficient specialization” in the labour market. This effect is also present in our model. However, by allowing for a direct disutility of housework (which is minimized – i.e. efficiency maximized- when there is equal split of housework) this second effect can dominate under some scenarios, leading to higher welfare in the symmetric equilibrium.

Some preliminary insight for the plausibility of our underlying mechanism can be obtained from a few scatter plots displaying aggregate cross-country correlations for ten European countries. We depict the correlations among the key variables in our model, that is, wage and housework gaps, and differences in training intensity.4 Figure 1 displays the scatter plot of the (residual) male-female gross hourly wage gap (vertical axis) against the female share of total housework (horizontal axis) in these countries. The reported wage gap is taken from the OECD Employment Outlook (2002, Ch. 2, Annex 2A, with data for the late 1990s and early 2000s). It is adjusted not only by the standard controls in mincerian wage equations, but also by country-specific wage dispersion (using Juhn et al. (1993)’s approach) to improve comparability of pay gaps across countries with different degrees of overall wage inequality. The female housework share data are obtained from the Multinational Time Use Survey (2003) and belong to the early 2000s (see Section 6 for a detailed discussion of this data source). There is a positive correlation (0.47) between both variables suggesting that in those

3 Moro and Norman (2003) examine a model of racial statistical discrimination with human capital investments and find that affirmative action may result in higher wage inequality across racial groups, in the spirit of Coate and Loury (1993)’s well-known result.

4 These countries are Belgium, Finland, France, Germany, Italy, Norway, Poland, Spain, Sweden and the UK. Only for this group of countries there is available information simultaneously in the three different data sources used to construct the data in the scatter plots.
countries where women allocate more time to household work, the unexplained gender wage gap is greater.

According to our theory, this positive correlation is driven by the correlations of the wage and housework gaps with training gaps. Figure 2 shows the scatter plot of the female housework share (horizontal axis) against a measure of the male-female gap in the intensity of paid-for training (vertical axis) in 2000, which is available from the European Working Conditions Survey (2002).\footnote{Specifically, this variable is computed using information drawn from the Third European Working Conditions Survey (2002, Annex 3, q28a). It corresponds to the male-female differences (measured in percent) in the proportion of time that workers report to have undergone paid-for training during the last month (i.e., the ratio between the proportion of hours of training and hours worked). For each country, the intensities are weighted by the incidence of training for each gender (i.e., the probability of being trained). Overall, this incidence is slightly higher for women than for men (27.1\% vs. 25.3\%), in agreement with the results in Arulampanam et al. (2004). The joint evidence of higher incidence and lower intensity for women has also been found in the US (see, e.g., Altonji and Spletzer, 1991 and O’Halloran, 2008).} As we predict, the correlation is strongly positive (0.87).\footnote{Note that, although training is the key channel which leads to wage differentials in our model, a similar interpretation could be obtained using the job-ladder allocation of workers analysed in Lazear and Rosen (1990) and even, albeit more loosely, in terms of the high segregation of women in college degrees with lower market returns despite the fact that they often perform better than men in high school (see Machin and Puhani, 2003).} Finally, Figure 3 displays the relationship between training and wage gaps, whose correlation is again positive (0.60). Therefore, despite the very limited number of observations in the plots and problems related to omitted variables and reverse causality, this preliminary evidence provides some support for the driving forces in our model. These shortcomings of using very aggregate data will be addressed later in Section 6, where we re-examine some of this evidence using micro data from time-use surveys for a small subset of the above-mentioned EU countries.

Figure 1: Relationship between (residual) wage gap and female share of housework

![Figure 1: Relationship between (residual) wage gap and female share of housework](source)

The remainder of the paper is organised as follows. Section 2 lays out the model. Section 3 discusses the properties of the different equilibria. Section 4 deals with welfare analysis. Section 5 analyses the effects of using different policies to eliminate the asymmetric equilibrium. Section 6 provides detailed empirical evidence on some of the main predictions of the model using micro data from time-use surveys in three European countries (Norway, Spain and the UK). Finally, section 7 concludes. Further data descriptions and some algebraic derivations are relegated to two Appendices.

2. Modelling gender gaps

2.1 The basic setup: A training model

To account for the joint presence of gender wage and housework gaps, we build a
The basic setup is as follows. *Ex ante* identical men and women live for two periods, each of which has a length normalized to 1. Each gender represents half of the overall population, whose size is also equal to 1. In period 1, firms are randomly matched with just one worker of either gender who is assumed to be single. All individuals receive an amount of (specific) training, $\tau$, provided by the firm which bear a linear training cost, $c(\tau)=\tau$. For simplicity, it is assumed that workers do not receive a wage during the training period. Finally, there is free entry of firms in period 1 until the expected profits from training workers are driven down to zero.

At the start of period 2, individuals of each gender form couples (exogenously) and decide on how to split the household chores on the basis of expected relative wages. Once this decision is taken, workers (ready to produce after being trained) are offered a wage, $W$, by the firm. After the wage has been announced, individuals suffer a disutility shock related to household tasks, $\omega$, which may force them to quit the job before they start producing. The $\omega$ shock is an *i.i.d.* random variable with c.d.f. $F(\omega)$, whose specific properties are discussed below in subsection 2.3. Individuals then decide whether to work or to quit. In the first case, production takes place and wages are subsequently paid by firms. Output per worker, denoted by $a$, depends on the level of training in period 1. The production technology is assumed to be $a(\tau) = \beta\tau^{\alpha/2}$, where $\beta > 0$ is a shift factor capturing the productivity level in the economy (say TFP) and $0 < \alpha < 1$, so that $a(\tau)$ is increasing ($a'(\cdot) > 0$) and strongly concave ($a''(\cdot) < 0$).

Since the amount of training determines workers’ productivity, firms will decide how much training to provide in period 1 and the corresponding wage in period 2, taking as *given* the decision about the allocation of time within couples once the household shock takes place. Conversely, husbands and wives bargain over the division of housework at the start of period 2 before the disutility shock is realized, taking as *given* the wages offered by firms to each of the partners. Accordingly, workers will always get trained in period 1 and they will not quit in period 2 insofar as $W - \omega \geq 0$. 
Summing up, the timing of decisions can be graphically represented as follows:

\[
\begin{array}{cccccc}
\text{t=1} & \text{t=2} \\
\hline
\text{Training} & \text{Household decision} & \text{Wage offer} & \text{Disutility shock} & \text{Production} \\
\uparrow & \uparrow & \uparrow & \uparrow & \uparrow
\end{array}
\]

2.2 Firms’ decisions

To solve for wages and the amount of training, we proceed backwards in time, first considering decisions in period 2 and later in period 1. To simplify the derivations, the distribution of shocks is assumed to be uniform, i.e., \( \omega \sim U[0, \epsilon \beta'] \) with \( \gamma \geq 0 \), \( 0 < \epsilon \leq 1 \) and \( 0 < \epsilon \beta' \leq 1 \). The last two inequalities ensure that the time allocation induced by the shock never exceeds the unit length available in period 2 even when \( \gamma = 0 \). The factor \( \beta' \) appearing in the upper bound of the support captures the fact that the size of the shock can be affected by the level of productivity. For example, it is conceivable that children’s minor health problems could be seen as a shock requiring parental time in richer economies (i.e., those with a higher value of \( \beta \)) but not in poorer ones. For \( \gamma = 0 \) the support of the shock is \([0, \epsilon]\) and hence independent of productivity, whereas \( \gamma > 0 \) implies a larger support in richer economies.

Under the assumption that the wage is announced before the disutility shock \( \omega \) is realized, firms choose the wage \( W \) in period 2 to maximize expected gross profit, \( \Pi \), given the probability that the worker may quit after being trained. This leads to the following optimization problem:

\[
\max_{W} \Pi \left( W \right) = \max_{W} \int_{0}^{W} \frac{1}{\epsilon \beta'} a(\tau) - W \, d\omega = \max_{W} \frac{a(\tau)W - W^2}{\epsilon \beta'},
\]

(1)

where the integral in the middle of (1) captures the expected profit achieved by the firm when the worker remains in the job after being trained. Hence, the first-order condition (henceforth, f.o.c.) with respect to \( W \) implies that the wage paid in equilibrium, \( W^* \), satisfies:

\[
W^*(\tau) = \frac{a(\tau)}{2},
\]

(2)

\footnote{This is just the average of the worker’s productivity and the outside wage, which is assumed to be zero. The weight \( \frac{1}{2} \) in the wage is due to the choice of the uniform distribution in the illustration. Alternative distributions will give rise to a weighted average with unequal weights.}
such that expected gross profit in period 2 is:

\[ \Pi(\tau) = [a(\tau) - \frac{a(\tau)}{2}] W^* = \frac{a(\tau)^2}{4\epsilon \beta^\gamma}, \]  

(3)

where the term \( W^*/\epsilon \beta^\gamma \) captures the probability of not quitting the job, i.e., \( \Pr(\omega \leq W) \).

Free-entry of firms implies that expected profits at the beginning of period 1 are driven down to zero due to decreasing returns to training. The zero-profit condition therefore pins down the optimal level of training in period 1, \( \tau^* \), given by:

\[ \Pi(\tau^*) - \tau^* = 0. \]  

(4)

Hence, under the functional form assumed for \( a(\tau) \), \( \tau^* \) is chosen to be:

\[ \tau^* = \left( \frac{\beta^{2-\gamma}}{4\epsilon} \right)^{1/\gamma}, \]  

(5)

so that, replacing (5) in (2), the optimal wage becomes:

\[ W^* = \frac{\beta}{2} \left( \frac{\beta^{2-\gamma}}{4\epsilon} \right)^{1/(1-\alpha)}. \]  

(6)

Thus, (5) and (6) imply that, as the support of the disutility shock becomes larger (i.e., \( \epsilon \beta^\gamma \) increases), workers face a higher probability of quitting in period 2 and, since this reduces expected profits, firms respond by lowering the amount of training and therefore wages. Note that our assumption that \( 0 < \alpha < 1 \) plays a crucial role in this result. If \( \alpha \geq 1 \) (i.e., if there were weak diminishing returns in training) then the firm would respond to a higher probability of quitting by increasing the amount of training, using the resulting wage rise to offset the higher expected value of the shock. Hence, our assumption of strong diminishing returns to training prevents this rather counterintuitive outcome.

From (6), one can also easily derive the probability of working \( (P^* = \Pr(\omega \leq W^*) = W^*/\epsilon \beta^\gamma) \) and the expected wage \( (P^* W^* = W^*/\epsilon \beta^\gamma) \) in equilibrium, which are given by:

\[ P^* = \left( \frac{\beta}{2} \right)^{1/(1-\alpha)} \left( \frac{1}{\epsilon \beta^\gamma} \right)^{2/(1-\alpha)}, \]  

(7)

\[ P^* W^* = \left( \frac{\beta^{2-\gamma}}{4\epsilon} \right)^{1/(1-\alpha)}. \]  

(8)
As before, a larger upper bound of the shock distribution, \( \gamma \beta' \), results in both lower participation and expected wage since \( \alpha \in (0, 1) \). Further, since the length of period 2 is equal to 1, the following assumption is needed to ensure that \( P^* \leq 1 \):

**Assumption 1:** The following inequality holds: \( \left( \frac{\beta^{2-\gamma}}{4\varepsilon} \right)^{\frac{1}{1-\alpha}} \leq \varepsilon \beta' \leq 1 \).

This assumption simply requires the productivity of training (\( \beta \)) not to be too large since, otherwise, the resulting wage would be sufficiently high (relative to the shock) to lead to excessive participation in the labour market. In what follows, we will denote \( \left( \frac{\beta^{2-\gamma}}{4\varepsilon} \right)^{\frac{1}{1-\alpha}} \) by the parameter \( b_1 \) which, by Assumption 1, verifies \( b_1 \leq 1 \). As a result, the equilibrium wage becomes \( W^* = \sqrt{\varepsilon \beta' b_1} \), implying that \( W^* \leq 1 \).

### 3. Household division of labour and multiplicity of equilibria

#### 3.1 Household division of labour

The next step is to endogenize the decision about how to split the household chores at the beginning of period 2 once couples are formed. We assume that there is a household good to be produced by the members of the household, and that this good provides a fixed utility level denoted by \( \bar{u} \). The couple jointly decides how to split the responsibility for production of this good by choosing a fraction \( s \in [0,1] \) of the household chores allocated to the wife and \( 1-s \) to the husband.

The production of the household good involves two disutility costs. Part of the cost is perfectly known in advance, while the remaining component is uncertain (stochastic) and depends on the uniformly distributed shock received by the household in period 2. To give an example of certain disutility costs, suppose that the household good consists of raising children. Children have to be collected from school and ferried to their after-school activities every day, imposing a (known) disutility cost to the parent in charge of this task, irrespective of whether he/she is employed or not. Additionally, there are shocks, such as a child becoming sick and needing to stay home with a carer. These impose an opportunity cost only if the parent is working since they imply a reduction in the (monetary) utility derived from the job.

---

\(^8\) Note that the random shock need not be solely related to the presence of children in the household. Another example would be someone having to stay at home waiting for a plumber to fix a leak, etc.
The certain and uncertain disutility costs of producing the household good are assumed to be identical. Besides the standard assumptions about disutility costs being increasing and convex in their respective housework shares, we assume that both spouses are essential inputs in the operation the household. In other words, their time allocation is such that they never fully specialize in either marketplace or housework activities, in accordance with the evidence on time-use surveys in developed countries where strictly positive housework shares are reported by both partners (see Section 6). Specifically, we choose the simple functional forms \((s^2 - 1)\) and \(((1-s)^{-1} - 1)\) for the husband’s and wife’s disutility, respectively. Thus, as the wife undertakes more housework, i.e., as \(s\) increases, her husband gets lower disutility, and vice versa. Yet if \(s = 0\) or \(1\) then the disutility of one of the partners becomes infinity. Finally, given that a fraction \(s\) (respectively \((1-s)\)) of the household shock is borne by the wife (husband), we will simplify notation by using in the sequel the subscripts \(m\) (male) and \(f\) (female) to denote the upper bounds of the support of the shock distribution affecting each gender, i.e., \(\varepsilon_f = se^\beta\) and \(\varepsilon_m = (1-s)e^\beta\). Similarly, wages will be denoted as \(W_f\) and \(W_m\).

Following the literature on collective decision making models (see, e.g., Chiappori, 1988, 1997), we further suppose that there is full income sharing within the household and that partners maximize the sum of utilities with respect to \(s\) taking their respective wages as given. Thus, the expected utility accruing to the household (net of costs), denoted by \(V^H\), is given by:

\[
V^H = \tilde{u} + \left[ \int_{0}^{w_f/(1-s)} \frac{W_m - (1-s)\omega}{e^\beta} \, d\omega + \int_{0}^{w_f/(1-s)} \frac{W_f - s\omega}{e^\beta} \, d\omega \right] - \left[ \frac{1}{s} + \frac{1}{1-s} - 2 \right],
\]

which, after integrating, becomes:

\[
V^H = \tilde{u} + \frac{1}{2e^\beta} \left[ \frac{W_m^2}{(1-s)} + \frac{W_f^2}{s} \right] - \left[ \frac{1}{s} + \frac{1}{1-s} - 2 \right]. \tag{9}
\]

The first term in the RHS of (9) represents the fixed utility from the household good, whereas the second and third terms capture, respectively, expected income (net of the random shock), and the disutility cost from producing the household good.

Under the previous assumption, there are two factors that drive the choice of \(s\). On the one hand, there are the convex costs of housework - the last bracketed term in (9) - which have an equalizing effect as total disutility is minimized when housework is
equally split \( (s = 0.5) \). On the other, there is a participation effect which leads to full specialization. To understand this effect, note that expected household income - the first bracketed term in (9)- is maximized when the member of the couple with the lower wage bears all the shock, the reason being that this ensures full labour market participation of at least one of the household members. Thus, the choice of \( s \) is driven by this trade-off between full specialization and equal share of housework.

Maximizing (9) with respect to \( s \) yields the f. o. c.:

\[
\frac{\partial V^H}{\partial s} = \frac{1}{2\beta} \left[ \frac{W_m^2}{(1-s)^2} - \frac{W_f^2}{s^2} \right] + \left[ \frac{1}{s^2} - \frac{1}{(1-s)^2} \right] = 0,
\]

which implies that the equilibrium share of housework, denoted by \( s^* \), is determined by equating the marginal rates of substitution between market work and household work, that is:

\[
\left( \frac{1-s^*}{s^*} \right)^2 = 1 - \frac{W_m^2}{2\beta} \frac{W_f^2}{2\beta}.
\]

Assumption 1 ensures that \( W_m^2 / 2\beta < 1 \). As a result, it follows that \( ds^* / dW_f < 0 \) and \( ds^* / dW_m > 0 \), implying that a higher female (male) wage leads to a reduction (increase) of the female housework share. Moreover, when wages are equalised, i.e., \( W_f = W_m \), then \( s^* = 1 - s^* = 0.5 \). This result is due to the symmetry assumption in the way in which we model the costs of housework (i.e., no comparative advantage of either gender), together with the fact that the convexity of the cost function implies that the total disutility cost is minimized when household chores are evenly split. Lastly, the partial equilibrium nature in (11) of the household’s decision implies that, for given relative wages, an increase in the support of the shock \( (\varepsilon \beta^r) \) decreases (increases) \( s^* \) whenever \( W_m > W_f \) (i.e., the case we will focus on), and conversely when \( W_m < W_f \).

The intuition for this effect can be found in (9): the higher is the upper bound, the lower is the expected income of the couple and, as a result, the spouses will prefer to share housework more evenly in order to maximize household’s utility. However, as will be shown below, the effect of \( \varepsilon \) on \( s \) in this partial equilibrium setup will change its sign once a general equilibrium analysis is undertaken.

\[\text{The fact that } \frac{W_f^2}{2\beta} \leq 1 \text{ also ensures that the second-order condition for a maximum is satisfied.}\]
3.2 Multiplicity of equilibria

Firms’ and households’ decisions are given by equations (6) and (11). In equilibrium expectations are fulfilled, and hence the equilibrium values of wages are housework shares are jointly determined as the solution of the following system of equations:

\[ W_f = \left( \frac{\beta^{2-\alpha}}{4\epsilon^{\frac{\alpha}{2}} s^\alpha} \right)^{\frac{1}{2(1-\alpha)}}, \quad \text{(E.1)} \]

\[ W_m = \left( \frac{\beta^{2-\alpha}}{4\epsilon^{\frac{\alpha}{2}} (1-s)^\alpha} \right)^{\frac{1}{2(1-\alpha)}}, \quad \text{(E.2)} \]

\[ \left( \frac{1-s^*}{s^*} \right)^2 = \frac{1-\frac{W_m^2}{2\epsilon \beta^2}}{1-\frac{W_f^2}{2\epsilon \beta^2}}, \quad \text{(E.3)} \]

To analyse the equilibrium configurations, it is useful to substitute (E.1) and (E.2) into (E.3), so that the f.o.c. (11) can be rewritten as:

\[ \left( \frac{1-s^*}{s^*} \right)^2 = \frac{1-b_2 (1-s^*)^{\frac{\alpha}{1-\alpha}}}{1-b_2 (s^*)^{\frac{\alpha}{1-\alpha}}}, \quad \text{(12)} \]

with \( b_2 = \left( \frac{\beta^{2-\gamma}}{4\epsilon^{\frac{\gamma}{2}}} \right)^{\frac{1}{2}} / 2 < 0.5 \), by Assumption 1. From (E.1) and (E.2), we can also define the gender wage and participation gaps as follows:

\[ w = \frac{W_m}{W_f} = \left( \frac{s}{1-s} \right)^{\frac{\alpha}{2(1-\alpha)}}, \quad P_m = \frac{P_m}{P_f} = \left( \frac{s}{1-s} \right)^{\frac{2-\alpha}{2(1-\alpha)}}. \quad \text{(13)} \]

To solve for \( s \) in (12), it is convenient to think of the following two functions:

\[ f(s) \equiv \left[ (1-s)/s \right]^2, \quad g(s) \equiv \left[ (1-b_2 (1-s)^{\frac{\alpha}{1-\alpha}})/(1-b_2 s^{\frac{\alpha}{1-\alpha}}) \right], \]

whose intersection results in the equilibrium allocation of housework. On the one hand, \( f(s) \) (which from (13) is an increasing transformation of the inverse of the gender wage gap) is decreasing and convex with a vertical asymptote at \( s=0 \), such that \( f(1) = 0 \) and \( f(0.5) = 1 \). On the other, \( g(s) \) is increasing in the range \( s \in [0,b_2^{\frac{1-\alpha}{\alpha}}] \) and decreasing when \( s \in (b_2^{\frac{1-\alpha}{\alpha}},1) \), with two vertical asymptotes at \( s = b_2^{\frac{1-\alpha}{\alpha}} \), and at \( s = 1 \), such that \( g(0) = 0 \), \( g(0.5) = 1 \) and \( g(1-b_2^{\frac{1-\alpha}{\alpha}}) = 0 \). Lastly, under Assumption 1, it can be checked that \( g(s) \) has an inflection point within the range \( s \in (b_2^{\frac{1-\alpha}{\alpha}},1-b_2^{\frac{1-\alpha}{\alpha}}) \).
The intersections of \( f(s) \) and \( g(s) \) are depicted in Figure 4 where the vertical axis represents the inverse of the wage gap in (13). As can be seen, there are three values of \( s \) that satisfy equation (12). In one of them, \( s_1^* = 0.5 \), while in the other two solutions we have \( s_2^* \in (0.5, 1 - \frac{1-\alpha}{\alpha}) \) and \( s_3^* \in (0, b_2 \frac{1-\alpha}{\alpha}) \). Note that corner solutions are ruled out by our assumption that disutility becomes infinite under complete specialization in housework.

**Figure 4: Gendered and ungendered equilibria**

Due to the assumption of symmetry across genders, two possible asymmetric equilibria exist: one in which women bear a greater share of housework and get a lower wage (point G), and another in which the same outcomes apply to men (point G’). In the sequel, we will solely focus on the historically more relevant case where women carry out a disproportionate share of the household chores, so that the permitted domain of the \( g(s) \) function becomes \( s \in (b_2 \frac{1-\alpha}{\alpha}, 1) = S \). This restricts the analysis to two possible equilibria, labelled respectively as the *gendered* equilibrium (denoted by G), where \( s_G^* > 0.5 \), and the *ungendered* equilibrium (denoted by U) where \( s_U^* = 0.5 \). Likewise, the gender wage gaps in these two equilibria are labelled as \( w_G^* \) and \( w_U^* \). The following result summarises this discussion:

**Proposition 2:** Under Assumption 1 and \( s \in S \), there are two equilibrium solutions for the female share of household work and the wage gap: (i) an ungendered solution with \( s_U^* = 0.5 \) and \( w_U^* = 1 \) and (ii) a gendered solution with \( s_G^* \in (0.5, 1 - b_2 \frac{(1-\alpha)/\alpha}{\alpha}) \) and \( w_G^* > 1 \).
To gauge how different these equilibria can be, let us consider the following numerical example. Using the parameter values $\alpha = 0.5$, $\varepsilon = 1$, $\gamma = 0$, and $\beta = 2^{3/4}$, which jointly satisfy Assumption 1, the roots of equation (12) become $s^*_G = 0.7236$ and $s^*_U = 0.5$. This leads to a wage gap in favour of men of 62% in the G-equilibrium, illustrating that the differences in the outcomes of the two equilibria could be very large.

### 3.3 The effect of the productivity level on equilibria

Inspection of (12) and Figure 4 indicates that the system in (E.1)-(E.3) may only exhibit a single equilibrium. Indeed, the existence of multiple equilibria crucially depends on the size of the $b_2$ parameter. In effect, as $b_2$ increases, the range $s \in \left( \frac{1}{\alpha}, 1 - \frac{1}{\alpha} \right)$ becomes narrower and, as a result, $g(s)$ becomes steeper. This shifts the G-equilibrium to the left with a more even division of housework, and hence a lower wage gap.

![Figure 5: The effect of an increase in $b_2$ on equilibria](image)

As depicted in Figure 5, for sufficiently high values of $b_2$, there will be a unique U-equilibrium. Since $b_2 = 0.5 \left( \frac{\beta^{2-\gamma}}{4 \varepsilon} \right)^{1/\gamma}$, its value depends on the productivity parameter $\beta$ and its power $\gamma$, and on the upper bound parameter $\varepsilon$. Notice that the effect of $\beta$ can be ambiguous: when $\gamma = 2$, $b_2$ is independent of $\beta$, while for $\gamma < 2$ we have $\partial b_2 / \partial \beta > 0$, and for $\gamma > 2$, $\partial b_2 / \partial \beta < 0$. By contrast, $\partial b_2 / \partial \varepsilon < 0$ holds unambiguously. These results are summarised in the following two propositions:
**Proposition 3a:** Under Assumption 1 and \( s \in S \), the effect of the productivity level \( \beta \) on the equilibrium gender gaps depends on the value of the parameter \( \gamma \):

(i) For \( \gamma < 2 \), the higher the value of \( \beta \), the lower are the equilibrium gender gaps. Moreover, economies with a sufficiently high value of \( \beta \) will exhibit a unique ungendered equilibrium.

(ii) For \( \gamma = 2 \), the value of \( \beta \) has no effect on the equilibrium gender gaps.

(iii) For \( \gamma > 2 \), the higher the value of \( \beta \), the larger are the equilibrium gender gaps.

**Proposition 3b:** Under Assumption 1 and \( s \in S \), a rise in the likelihood of suffering a disutility shock driven by parameter \( \varepsilon \) increases the equilibrium gender gaps.

To understand the intuition behind Proposition 3a, consider the case with \( \gamma = 0 \), where the only effect of a rise in \( \beta \) is to raise wages. The reason why productivity matters is that it creates an income effect. Recall that the household faces a trade-off between expected income and housework disutility: the former effect implies that income is higher with full specialization \((s=1)\), while the latter tends to induce an even allocation of housework across genders \((s=0.5)\). When wages are low \((\beta \text{ is small})\), the household is less willing to forgo expected income in order to reduce the disutility cost. Hence, if firms offer different wages, housework will be unevenly allocated. By contrast, when wages are high \((\beta \text{ is large})\), the household is more willing to forgo expected income in order to reduce the disutility cost, leading to a lower \( s^*_G \). If wages are sufficiently high, the disutility effect dominates, making the housework division (almost) even when wages differ across genders.\(^{10}\) But if \( s \) is (close to) 0.5, then firms will pay similar wages to men and women. Hence the G-equilibrium cannot exist.

Consider now the more general case in which the support of the shock is affected by productivity. For given wages, a higher value of \( \beta \) implies a larger expected shock, lower labour-market participation and hence lower expected income for any division of housework. The resulting income effect would tend to foster specialisation and increase \( s^*_G \). When \( \gamma > 0 \), the overall income effect has two elements:

---

\(^{10}\) To see this simply let \( b_2 \to \infty \) in equation (12), which makes its RHS equal to 1, implying that \( s=0.5 \).
higher productivity increases wages but it also increases the shock and reduces participation for given wages. Which of the two effects dominates depend crucially on the size of $\gamma$. For $\gamma < 2$, the wage effect dominates and hence higher productivity increases expected income and reduces the gender gaps. Conversely, for $\gamma > 2$, i.e. when higher productivity results in a sufficiently large increase in the shock, the participation effect dominates the wage effect. A larger value of $\beta$ then implies lower expected income and results in greater household specialisation and larger gender gaps. In principle, either of the two scenarios is possible. Note, however, that $\gamma > 2$ requires a very strong effect: since output increases linearly with $\beta$, it implies that higher productivity has a much larger effect on household shocks than on production. Moreover, from equation (6), it also implies the rather extreme result that that higher productivity is associated with lower levels of training.

As regards Proposition 3b, notice that, under a general equilibrium approach, the unambiguously increasing effect of $\varepsilon$ on the equilibrium gender gaps implies the opposite result of what we obtained before in (11) under a partial equilibrium analysis (i.e., for given wages), in which a larger value of $\varepsilon$ led to a lower gaps. The intuition is similar to that used for $\beta$ when $\gamma > 2$.

In sum, productivity plays a crucial role in determining the equilibrium gender gaps in wages and time allocation. It has been shown that a higher value of $\beta$ can increase or reduce these gaps. In the more plausible case of $\gamma < 2$, the gender gaps will be lower in more productive economies. Interestingly, this result on its own suggests that, abstracting from the differences in the use of family-aid policies, the lower gender gaps reported in Figure 1 for the Nordic than for the Southern European countries could be related to the higher productivity in the former.

4. Welfare analysis

In order to analyze the welfare implications of the two above-mentioned equilibria, let us consider the problem faced by a social planner who chooses the allocation of housework internalizing its effect on wages. Since firms make zero expected profits due to the free-entry assumption, aggregate welfare, denoted by $V^W$, is simply equal to the welfare of the representative household. Thus, substituting (E.1) and (E.2) into (9), yields the following social planner’s welfare function:
\[ V^W(s) = \bar{u} + \left[ b_2 (1-s)^{\frac{1}{1-\alpha}} + b_3 s^{\frac{1}{1-\alpha}} \right] - \left[ \frac{1}{s} + \frac{1}{1-s} - 2 \right]. \]  

(14)

We can now examine which of the two equilibria results in a higher level of welfare by substituting the f. o. c. (12) of the household into (14), which yields:

\[ V^W(s^*) = \bar{u} + 2 - \frac{1 - b_2 s^*^{\frac{\alpha}{1-\alpha}}}{(s^*)^2}. \]  

(15)

Then, differentiation of (15) implies:

\[ \frac{dV^W(s^*)}{ds^*} = \frac{1}{s^3} \left[ 2 - \frac{2 - \alpha}{1 - \alpha} b_2 s^*^{\frac{\alpha}{1-\alpha}} \right], \]

which may be positive or negative depending on the sign of the bracketed term. Hence, it is ambiguous whether welfare is higher in the G- or in the U-equilibrium. The reason for this ambiguity is again the trade-off between full specialisation and equal sharing of housework.

Once more, the level of productivity \( \beta \) is a key parameter determining which effect dominates: Since \( b_2 \) is increasing in \( \beta \) in the more realistic case where \( \gamma < 2 \), \( s^*_G \) will decrease with the productivity level. Hence, \( dV^W(s^*)/ds^* < 0 \) for sufficiently high values of \( b_2 \) driven by a rise in \( \beta \). Because \( s^*_G > s^*_U = 0.5 \), this leads to higher welfare in the U-equilibrium. To illustrate this result, consider again our previous numerical example with the two equilibria given by \( s^*_G = 0.7236 \) and \( s^*_U = 0.5 \). If we further assume that \( \bar{u} = 10 \) then, substituting the chosen parameter values into (15), we obtain a level of welfare in the G-equilibrium, \( V^W(s^*_G) = 3.2 \), which is lower than in the U-equilibrium, \( V^W(s^*_U) = 4.1 \). Conversely, it can be easily shown that lower values of \( \beta \) (yet satisfying Assumption 1) would yield an opposite welfare ranking.

This finding contrasts with the results in the literature on this type of multiple equilibria, where it has generally been found that specialization results in higher welfare.\(^{11}\) The difference lies in the symmetric way we have modelled the disutility cost associated with housework. Moreover, our analysis has the implication that the nature of the efficient equilibrium may change over time. Suppose that the productivity parameter grows exogenously. Initially, when \( \beta \) is low, specialization delivers higher welfare.

\(^{11}\) An exception is the model proposed by Lang at al. (2005) about racial discrimination in labour markets due to posted wage offers, where it is shown that discrimination creates economic inefficiency. However, their setup is quite different from ours since they assume that the posted wage offers are exogenous.
Yet, as productivity grows, the opportunity cost of sharing housework falls and the U-equilibrium becomes more efficient.\footnote{For analyses of how exogenous changes in productivity affect gender differences in the labour market, see Olivetti (2006) and Albanesi and Olivetti (2009).}

5. Policies: Family aid and affirmative action

In this section we discuss which type of gender policies could shift the economy from the G-equilibrium to the U-equilibrium. In line with an extensive literature on this issue, we focus on two specific policies: (i) subsidised family aid, and (ii) affirmative action.

5.1 Subsidised family aid

5.1.1 Gender-based vs. Gender-neutral family aid

Consider the introduction of government-funded family aid. To start with, suppose that only working women receive the subsidy, and that this subsidy, $\kappa$, is proportional to their wage in period 2. Thus, women will receive an income equal to $W_f (1 + \kappa)$, where $0 < \kappa < 1$, so that they will not quit in period 2 if $W_f (1 + \kappa) - \omega \geq 0$. Men do not receive the subsidy and therefore they work if $W_m - \omega \geq 0$. For the time being, we concentrate on the partial equilibrium effect, ignoring the financing of the subsidy, an issue which will be examined at the end of this section.

Following the analysis about firms’ behaviour in section 2.2, but this time with the upper limit of the integral for women in (1) changed from $W_f$ to $W_f (1 + \kappa)$, it follows that firms will choose the following amount of training and wages:

$$\tau_f^{eq} = \left( \frac{(1 + \kappa) \beta^2}{4 \ell_f} \right)^{\alpha/2}, \quad W_f^{eq} = \frac{\beta}{2} (\tau_f^{eq})^{\alpha/2},$$

(16)

where the superscript $\kappa$ is used to denote the equilibrium values under subsidies. Male workers are offered the training level and wage derived in (5) and (6). Note that the total income of women in period 2, $Y_f^{eq}$, is now given by:

$$Y_f^{eq} = (1 + \kappa) W_f^{eq} = \frac{\beta(1 + \kappa)}{2}(\tau_f^{eq})^{\alpha/2}.$$  

(17)

Not surprisingly, women fare better in the labour market when they are subsidised to stay in the job since $\tau_f^{eq} > \tau_f^{*}$ and $W_f^{eq} > W_f^{*}$, despite the fact that,
for \( \kappa < (\varepsilon_f - \varepsilon_m)/\varepsilon_m \) (i.e. if the subsidy is not too large), they still receive less training and lower wages than men, that is, \( \tau_f^{ss*} < \tau_m^{ss*} \) and \( W_f^{ss*} < W_m^{ss*} \).\(^{13}\) They may even get higher gross wages than men if the subsidy is sufficiently large but this possibility is we ignored in the sequel.

Abstracting from the household decision, (16) an (17) imply that the corresponding participation and wage gaps would be lower than without subsidies. However, this result does not hold once the division of housework is endogenized. In effect, each household chooses \( s \) to maximize the expected net utility which is now given by:

\[
\bar{V}_{Hs}^* = \bar{u} - 2 + \frac{1}{2\varepsilon \beta^r} \left[ \frac{W_m^2}{(1-s)} + \frac{Y^{\kappa_2^2}}{s} \right] - \left[ \frac{1}{s} + \frac{1}{1-s} \right].
\]  

(18)

The resulting f. o. c., once we have substituted for wages, yields the new equilibrium relationship:

\[
\left( \frac{1-s^{ss*}}{s^{ss*}} \right)^2 = \frac{1-b_2(1-s^{ss*})^{-\alpha}}{1-b_s s^{\kappa-\alpha}}
\]  

(19)

where \( b_1 = b_2 (1+\kappa)^{1/\alpha} > b_2 \). The LHS of equation (19) is the same as in (12), while the RHS tilts upwards and takes a value greater than 1 when \( s=0.5 \). The new equilibrium is depicted in Figure 6 and can be summarised as follows:

**Proposition 4:** Under Assumption 1 and \( s \in S \), a wage subsidy to female workers leads to a gendered equilibrium with \( s^{ss*} \in (0.5, 1) \). The equilibrium division of household work implies a higher share for women, and hence larger wage and housework gaps than in the absence of the subsidy.

---

\(^{13}\) In equilibrium, since \( \varepsilon_f = \beta^r \varepsilon \) and \( \varepsilon_m = (1-s) \beta^r \varepsilon \), this condition becomes \( \kappa < 2s - 1 \).
A surprising feature of (19) is that, with the subsidy in place, the U-equilibrium with \( s = 0.5 \) no longer exists. In other words, a gender-based subsidy policy only yields the G-equilibrium since the asymmetry in income induced by the subsidy prevents a symmetric equilibrium. In effect, suppose that households set \( s = 0.5 \). Then women have a lower probability of quitting than men (the combination of the same shock plus the subsidy), implying that firms will offer women more training and a higher gross wage. But if female wages are different from men's, then \( s = 0.5 \) cannot be a solution to the household's problem. Hence, the U-equilibrium disappears. Moreover, it can be easily shown that the new G-equilibrium in Figure 6 lies to the right of the initial one in Figure 4, leading to a higher equilibrium value of \( s \). For example, using our previous choice of parameter values but this time with \( \kappa = 0.1 \), yields \( s^* = 0.7299 > s^*_G = 0.7236 \). To understand this result, recall one again the trade-off faced by the household between increasing expected income and reducing the disutility of housework. Because the subsidy increases the probability of female labour participation, the household can now afford to raise the probability of male participation by reducing their housework share. This result shares the spirit of the analysis of affirmative action policies in Coate and Loury (1993) where it is argued that an exogenous increase in the hiring probability faced by a minority would reduce their educational effort and hence increase the educational gap. Similarly, in our framework the exogenous increase in the probability of participation of women reduces their commitment to the labour market.

By contrast, consider now an alternative policy which offers the same subsidy to men and women. Following the same reasoning as above, this would yield the equilibrium relationship:
\[
\left(\frac{1-s^{s^{*}}}{s^{s^{*}}}\right)^2 = \frac{1-b_3(1-s^{s^{*}})^{1-a}}{1-b_3s^{s^{*}}(1-a)} ,
\]
which will again narrow the range of values of \( s \) for which the RHS of (20) is positive, since \( b_3 > b_2 \). The first implication is that the subsidy shifts the G-equilibrium to the left, reducing the value of \( s^*_G \). Moreover, if the subsidy is high enough (i.e. if \( b_3 \) is sufficiently large), equation (20) will exhibit a unique U-equilibrium, as in Figure 4, with higher participation rates and wages of both genders than under laissez-faire. Once more this is the result of the trade-off between higher expected income due to specialization and lower disutility due to the sharing of housework. The subsidy effectively increases expected income and hence reduces the opportunity cost of sharing housework. If the increase in income is large enough, the household will simply minimize the disutility associated with housework and choose equal sharing of domestic tasks. This reasoning in favour of neutral-gender subsidies also echoes some of Saint-Paul (2007)’s recent arguments against gender-based taxation.

5.1.2 Financing the subsidy

We next consider the financing of the subsidy. It is clear from the earlier discussion that a female wage subsidy financed by taxing men will lead to an asymmetry in the RHS of (19) eliminating therefore the U-equilibrium. Instead, we suppose that firms are taxed for their training expenditures in period 1 at a proportional rate \( t \).\(^{14}\) Under a balanced government budget, this implies that

\[
n(1+b) + \tau = \kappa ,
\]

In this tax-subsidy scheme, denoted by the superscript \( T \), participation is given by \( P_i^{T} = (1+\kappa)W_i^{T} / \epsilon_i \), and firms offer the wage \( W_i^{T}(\tau_i) = a(\tau_i) / 2 \), implying that gross profits become:

\[
\Pi(\tau_i) = \frac{a(\tau_i)^2}{4\epsilon_i}(1+\kappa),
\]
whilst the zero-profit condition for firms yields:

\[
\Pi(\tau_i) - (1+t)\tau_i = 0 .
\]

Noticing that we can write \( \Pi(\tau_i) = P_iW_i \), this condition is simply equivalent to

\(^{14}\) We have also examined the case where the tax is lump-sum in the first period. This case yields similar results though the calculations are somewhat more complex.
\( \tau_j(1+t) = PW_j \), which can be replaced into the budget constraint to obtain the equilibrium relation between the tax and the subsidy rates, i.e., \( t = \kappa/(1-\kappa) \). The zero-profit condition, together with this value of \( t \), yields the optimal level of training:

\[
\tau_j^{*} = \left[ \frac{2(1+\kappa)}{4\varepsilon_j(1+t)} \right]^{1/\alpha} = \left[ \frac{2(1-\kappa^2)}{4\varepsilon_j} \right]^{1/\alpha}.
\] (23)

Equation (23) implies lower training and wages than without subsidies as a result of the labour tax paid by firms. Participation, given by \( P_i^{*} = (1+\kappa)W_i^{*}/\varepsilon_i \), may be higher or lower than under laissez-faire due to the opposite effects of the subsidy and the lower wage. The former tends to increase participation while the latter tends to reduce it.

As regards the household decision on \( s \), a similar argument as before yields the following f.o.c.:

\[
\left( \frac{1-s^{*}}{s^{*}} \right)^2 = \frac{1-b_4(1-s^{*})^{\alpha}}{1-b_4s^{*}}.
\] (24)

where \( b_4 = b_2h(\kappa) \) with \( h(\kappa) = [(1-\kappa)^\alpha (1+\kappa)]^{1/\alpha} \). Then, \( h(0) = 1 \) and \( h'(\kappa) > 0 \) if and only if \( \kappa < (1-\alpha)/(1+\alpha) \). Thus, for not too high values of \( \kappa \), \( h(\kappa) \) is increasing and therefore \( b_4 > b_2 \). Hence, this tax-subsidy scheme makes the \( g(s) \) function steeper, implying that the equilibrium value of \( s \) will decrease and, potentially, a unique U-equilibrium could be achieved. Indeed, for the G-equilibrium to disappear, we also need that there is a unique intersection, which will be the case if \( 1-b_4^{(1-\alpha)/\alpha} \leq 0.5 \), that is, if \((1+\kappa)(1-\kappa)^\alpha \geq 2^{3-2\alpha} \varepsilon/\beta^2 \). Hence, the following result holds.

**Proposition 5:** Under Assumption 1 and \( s \in S \), if \( \kappa \) is not too large, i.e., \((1+\kappa)(1-\kappa)^\alpha \geq 2^{3-2\alpha} \varepsilon/\beta^2 \), an equal wage subsidy to male and female workers financed with a proportional tax on training expenditures by firms in period 1 will reduce gender gaps and may even lead to an ungendered equilibrium with \( s^{*} = 0.5 \).

The intuition for this result relies on the two conflicting effects affecting participation: a direct effect from the subsidy which tends to increase participation, and an indirect one operating through the reduction of training induced by the tax paid by
firms, which tends to reduce participation. The condition \( (1 - \alpha)/(1 + \alpha) > \kappa \) is easy to interpret since, from (24), a low value of \( \alpha \) implies a low elasticity of training with respect to the subsidy. This means that the wage does not fall by much and the direct effect dominates, leading to higher expected income for any given division of housework. As in section 3.3, a higher income implies that couples can afford to reduce the disutility cost of housework thereby choosing an equal split.

5.2. Affirmative action

An alternative policy is to impose by law an affirmative action rule that prevents firms from engaging in statistical discrimination. In our setup, this type of discrimination appears because firms provide different amounts of training to men and women. Consider now a policy that forces firms to post the amount of training they will provide before they are matched with a candidate. Recalling that all individuals get trained in period 1 and that the population is equally split across genders, the expected profit of a firm is given by:

\[
\Pi(\tau) = \frac{1}{2} \left( \frac{a(\tau)^2}{4\epsilon_f} + \frac{a(\tau)^2}{4\epsilon_m} \right). \tag{3'}
\]

Then, the zero-profit condition \( \Pi(\tau^a) - \tau^a = 0 \) pins down the optimal level of training in period 1 under affirmative action, \( \tau^a \), yielding:

\[
\tau^a = \left[ \frac{\beta^2}{8} \left( \frac{1}{\epsilon_f} + \frac{1}{\epsilon_m} \right) \right]^{\frac{1}{1-\alpha}}. \tag{5'}
\]

Since men and women receive now the same amount of training, (2) implies that they also receive the same wage. Turning to the couple’s division of household work, from the f.o.c. in (E.3), equal wages imply equal sharing of housework tasks. Hence, the only possible equilibrium is \( s = 0.5 \). Note that this implies that it is optimal for the firm to offer the same amount of training to both genders. In other words, since the reason for the existence of the U- equilibrium is a coordination problem, affirmative action will coordinate firms and households on the U- equilibrium in which firms would choose not to differentiate between genders even if they could.

There is an extensive debate on the effects of affirmative action policies. As discussed before, Coate and Loury (1993) show that an exogenous increase in the hiring probability reduces the educational effort of the minority. However, Moro and Norman
(2003) find that this result crucially depends on assuming that the marginal product of labour is constant for each type of workers. By contrast, when the marginal products depend on the relative supply of the two groups, general equilibrium effects imply that the changes in wages resulting from an affirmative action policy may induce minority workers to increase, rather than decrease, their educational investment. Our analysis illustrates how, even in the case where these externalities are absent, targeted policies towards statistically discriminated groups, can have different effects. Thus, while affirmative action in the form of equal access to training increases wages but does not have a direct effect on participation (i.e., it generates no disincentive effects), our previous analysis a subsidy that encourages the participation of women may induce a substitution effect that results in increased inequalities across groups.

Another recurrent issue in the literature is whether or not affirmative action policies need to be permanent or whether a one-shot policy can permanently reduce gender gap (see Coate and Loury, 1993). The fact that multiplicity is mainly due to a coordination problem in our setup implies that a one-period policy will change the equilibrium permanently. Imposing equal amounts of training for men and women changes the household decision problem and results in equal sharing of household tasks. Once firms observe $s=0.5$ and couples are paid equal wages, there is no reason for either of them to expect a different outcome even if the affirmative action policy were to be removed. Hence, the economy will remain in the U-equilibrium.

5.3. Asymmetric economies

Our framework makes the strong assumption of complete symmetry between men and women, and it is precisely this assumption that allows for the existence of U-equilibria. In this section we briefly examine how results get modified when we assume that there is an (exogenous) asymmetry associated to gender.

There are many ways of allowing for asymmetries, ranging from differences in comparative advantage in home/market production to the structure of intra-household bargaining. For simplicity, we focus on the latter and assume that men have higher bargaining power in the household decision-making process, denoted by $\eta$, so that household utility can be expressed as:

$$
\nu^{HI} = u + \frac{1}{2} \beta^{\eta} \left[ \frac{(1+\eta)W^2_m}{(1-s)} + \frac{(1-\eta)W^2_f}{s} \right] \left[ \frac{1+\eta}{s} + \frac{1-\eta}{1-s} - 2 \right].
$$

25
with \( \eta \in (0,1) \). The resulting f. o. c. together with the expressions for wages in (2) imply that equilibrium is given by:

\[
\left( \frac{1-s^*}{s^*} \right)^2 = \frac{1-\xi b_2(1-s^*)}{\xi - b_3(s^*)} = \frac{\alpha}{1-\alpha},
\]

(25)

where the relative bargaining power \((1+\eta)/(1-\eta)\) is denoted by \(\xi > 1\). The LHS of this expression is the same as in the symmetric case, while the RHS, i.e. the \(g(s)\) function, shifts upwards when compared to equation (12). As a result, when \(s=0.5\), \(g(s)\) takes a value greater than 1, implying that the U-equilibrium cannot exist.

Because the household gives greater weight to the disutility of the man, even when wages are the same across genders, women will end up doing more than half of the housework. But as women are bearing a greater fraction of the shock, firms will pay lower wages to them. Hence only the G-equilibrium exists.

Under this asymmetric case, a wage subsidy targeted to women can work. In effect, a subsidy equal to \(\kappa W_s f\) paid to participating women yields the following f. o. c.:

\[
\left( \frac{1-s^*}{s^*} \right)^2 = \frac{1-\xi b_2(1-s^*)}{\xi - b_3(s^*)} = \frac{\alpha}{1-\alpha},
\]

(26)

where the superscript \(\kappa, \eta\) denotes the case with asymmetric power and subsidies, and \(b_3 = b_2 (1+\kappa) \). Thus, one could choose \(\kappa\) so as to make the right-hand-side of (26) equal to 1 when \(s=0.5\), yielding:

\[
(1+\kappa) = \left( \xi + \frac{\xi - 1}{\alpha b_2 2^{1-\alpha}} \right)^{1-\alpha},
\]

so that the f. o. c. in (26) becomes:

\[
\left( \frac{1-s^*}{s^*} \right)^2 = \frac{1-\xi b_2(1-s^*)}{\xi - b_3(s^*)} = \frac{\alpha}{1-\alpha},
\]

(27)

Comparison of (27) and (12), under the same reasoning as in (24), implies that the U-equilibrium becomes more likely. Whether it is a unique equilibrium or not hinges on the sizes of \(\xi\) and \(b_2\), which in turn depend upon \(\eta\) and \(\beta\) (for given values of \(\alpha\) and
This result somewhat mimics the argument made by Alesina et al. (2007) in their proposal of different taxation for men and women. In their reasoning, the asymmetry across genders is that women have higher elasticity of labour supply than men and, therefore, in line with to the Ramsey principle of optimal taxation, the former should have lower taxes than the latter. In our setup, the asymmetry arises from different bargaining power but the policy implication is similar. Notice, however, that (27) also implies the novel result that, for given $\eta$, this gender-based taxation scheme is bound to be more effective in achieving the U-equilibrium in more productive economies (those with higher $\beta$), as long as $\gamma < 2$, than in less productive ones.

6. Some empirical micro evidence

6.1. Data and descriptive statistics

Simple cross-country correlations were presented in the Introduction to motivate our modelling approach. However, given that wages and housework shares are simultaneously determined in equilibrium, analysing aggregate cross-country data in more detail would involve having to tackle serious endogeneity problems. In order to somewhat overcome these problems, we focus in this section on the empirical modelling of the time allocation decision from the perspective of the household. Therefore, we abstract from the decisions taken by the firms in which they work about training and wage offers for which, lacking matched employer-employee data, information is not available. However, despite the limitation of adopting a partial equilibrium approach, we will show that it is still possible to empirically test several interesting theoretical predictions of our model. For that, we make use of micro data at the household level (two-earner couples) drawn from time use surveys carried out in several countries. The idea is that since, at the individual level, it is reasonable to assume that the spouses’ wages are taken as parametric by households, this will allow us to interpret wages as predetermined variables to the spouses’ choice of housework shares. More specifically, the data comes from the Multinational Time Use Survey (MTUS, see below for details) which contains information on the use of time by households living in a variety of countries. Given that external researchers have limited access to this data set, empirical evidence will only be presented for a subgroup of three European countries which we have selected on the basis of exhibiting rather different characteristics regarding gender gaps and the availability of policies to reconcile family
and market-work life. These countries are: (i) Spain, as a representative of Southern-European economies with less generous family-aid policies (data available for 2002-03)\(^{15}\), (ii) Norway, capturing the generous family-aid policies typical of the Nordic area (data is available for 2000)\(^{16}\), and (iii) the UK, a country in a somewhat intermediate situation (data is also available for 2002-03)\(^{17}\).

MTUS contains harmonized data on how much time each individual devotes to a wide range of (41) activities on a representative day. For each 10 minutes interval (and during 24 hours), respondents are asked to keep a diary recording which are the primary and secondary activities which they have undertaken. These are coded according to a list provided in Table A1 in Appendix.1. Housework time is defined as the number of minutes reported in the diary that each individual devotes to categories AV7 (housework) as primary activity. Likewise, this definition can be extended to include time devoted to childcare (housework plus childcare), in which case AV7 and AV11 are added. The partners’ shares of household work within each couple are computed for each of the two definitions.

In addition to time use, MTUS provides information on basic demographic and labour-market characteristics of the respondents. We restrict our sample to two-earner couples where both partners (living in the same household) have a full-time job,\(^ {18}\) belong to the 25-64 age bracket, and report complete information on housework share, wages and the remaining controls. Notice that the fact that part-time rates are much higher in Norway and the UK than in Spain implies that our sample sizes of full-time working couples are quite smaller for the first two countries.

One important limitation of MTUS is that it lacks information on the availability of family-aid subsidies, domestic service and the region of residence of the households. This can be restrictive since, on the one hand, we will not be able to test predictions about the different effects of family-aid, depending on whether it is gender-targeted or neutral (see however the informal discussion in subsection 6.3) and, on the other, we may suffer from omitted variables bias because the productivity parameter (\( \beta \)) at the

\(^{15}\) Italy could have been another representative of South-Mediterranean countries. However, MTUS does not contain information on wages for this country.

\(^{16}\) Access to MTUS micro-data from other Nordic countries, such as Finland or Sweden, is restricted. Regarding Denmark, the last year for which availability of the micro-data is provided is 1987.

\(^{17}\) Results for Germany (available upon request) were similar to those for the UK, and hence are not reported.

\(^{18}\) We exclude part-time workers since working hours (taken as fixed in our model) are jointly determined with hours of housework and this would create a bias. Moreover, the decision by firms on the intensity of training received by workers is likely to depend on whether their labour contract is full time or part time.
individual level is likely to be highly correlated with aggregate productivity level at the region of residence level and also with with the availability of domestic help. Fortunately, we could retrieve some information about these missing variables from the larger questionnaire used in the Spanish Time Use Survey (STUS), which is the domestic survey carried out in Spain from which the MTUS harmonized data for this country is drawn. This information, however, is not available in the corresponding domestic surveys carried out in Norway and UK. Thus, only for the case of Spain we will be able to later extend the analysis including these extra variables.

Table 1 presents descriptive statistics of the demographics (education levels and presence of children) and wages of the individuals in our sample, in addition to the extra variables available for Spain. Net hourly wages, expressed in the countries’ respective currencies, have been computed from reported net monthly wages and (four times) weekly working hours.

Source: MTUS. Data for Spain and for the UK is for 2002-2003. Data for Norway is for 2000. (*) denotes the percentage of couples who receive some type of state-funded family aid and of those who have domestic service; information on these two variables is only available for Spain (STUS, 200-03).
The average (log) wage gap higher in Spain, closely followed by the UK, and quite lower in Norway. As regards gender differences in spouses’ educational attainments, they are small in the three countries, whilst the proportion of individuals with a college degree is higher in Norway and Spain than in the UK. Next, the fraction of households with no children is higher in Spain and lower in Norway than in the UK, a ranking which matches the observed fertility rates in these countries. Finally, 26% the Spanish households have domestic service and 4% receive some form of family-aid subsidies.

Table 2 reports the female shares using the two above-mentioned definitions of household work. Spain exhibits the highest shares (80% and 76%) whereas Norway has the lowest (60% and 59%), and the UK (72% and 71%) is in between. By age and education, we find that it is lower for younger and more educated women, especially in Spain and the UK. To the extent that younger and highly-educated individuals tend to receive better training, this provides somewhat support for the result in Proposition 3a about the effect of productivity on gender gaps.

Note: Standard errors in parentheses. The definition of less-educated couples is that both partners have less than a college degree, while highly-educated couples are those where both partners have a college degree.

6.2. Testable implications

Since MTUS data refers to households’ decisions, our empirical application focuses on the structural equation given in (11) describing the decision of how to allocate housework within the household, using the two above-mentioned definitions of
housework shares. To obtain an estimable regression model, we use a log-linearization of (11) around a generic (possibly gendered) equilibrium value which, under the assumption that wages can be taken as parametric by the household, could be estimated by OLS (with heteroskedasticity-robust standard errors). This approximation yields (see Appendix 2):

\[
\ln \left( \frac{s}{1-s} \right) = \theta_0 + \theta_1 (\ln W_m - \ln W_f) + \theta_2 \ln W_f + \theta_3 \ln \beta + \theta_4 \ln \varepsilon, \tag{28}
\]

where the logit transformation of the dependent variable is always feasible since \(s\) is never equal to 0 or 1 in our three samples. The first set of testable implications relates to the signs and relative sizes of some of the parameters in (28) which satisfy the following restrictions: \(\theta_1 > \theta_2 > 0, \quad \theta_3 < 0, \quad \text{and} \quad \theta_4 < 0\) (see Appendix 2). Thus, as expected, the impact of the male wage (given by \(\theta_1\)) on the relative share is positive, i.e., a rise in \(W_m\) increases \(s\), whereas the corresponding impact of the female wage (given by \(\theta_2 - \theta_1\)) is negative, i.e., a rise in \(W_f\) decreases \(s\). Moreover, \(\theta_2\) is predicted to be smaller in those economies where gender gaps are closer to the ungendered equilibrium, that is, \(\theta_2 \uparrow 0\) as \(s^* \uparrow 0.5\). Summing up, we predict that, in economies with sizeable gender gaps in favour of men, there will be an asymmetric effect of the spouses’ wages on \(\ln(s/(1-s))\) whereas in economies with low gender gaps the effect will be more symmetric so that only the wage gap will appear as an explanatory variable. A second testable prediction relates to comparing the sizes of the coefficients in the two above-mentioned definitions of household work. In effect, since it is plausible that disutility shocks are likely to be more frequent in households with children, we would expect the estimated coefficients in (28) to be more sizeable for the definition of household work that contains childcare. Finally, the third testable implication relies on comparing the signs of the estimated coefficients on the variables capturing \(\ln \varepsilon\) in (28), i.e., children age status, with those obtained from a reduced-form specification where wages are omitted from the list of covariates in (28). The latter could be interpreted along the lines of

\[19\] However, it could be argued that male and female wages might be endogenous for the female housework share if unobserved individual characteristics are positively correlated with these wages gap, thus creating spurious correlation between these covariates and the error term. We have tried to instrument the wage gap and the female wage in (28) with third-order polynomials in age and education as in Mroz (1987). However, the correlations between these variables and the logged wages are rather weak, preventing them from being used as suitable instruments. Unfortunately, MTUS does not contain any other variables that can be used as adequate instruments for the gender wage gap.
of a similar log-linearization of (12) around a generic reference value of $s$, once the spouses’ wages have been properly endogenised as a result of firms’ beliefs. This yields the following equation:

$$\ln\left(\frac{s}{1-s}\right) = \phi_0 + \phi_1 \ln\beta + \phi_2 \ln\varepsilon,$$

(29)

where the discussion in subsection 3.3 about the general equilibrium effects of $\beta$ and $\varepsilon$ on $s$ implies that $\phi_1 \leq 0$ (if $0 \leq \gamma < 2$) or $\phi_1 > 0$ (if $\gamma > 2$) and $\phi_2 > 0$. As a result, if we find that $\phi_1 < 0$ when estimating (29), this result would confirm that $\gamma \in (0, 2)$ and therefore that higher productivity on its own can be a relevant factor explaining the reduction of gender gaps. Notice also that the prediction of $\phi_2 > 0$ in (29) under general equilibrium implies the opposite sign of the coefficient on $\ln\varepsilon$ in (28) under partial equilibrium, where $\theta_4 < 0$. Thus checking whether the coefficient on $\ln\varepsilon$ changes from being negative in (28) to being positive in (29) constitutes our last testable prediction.

Before we discuss the results, the issue of how we measure the covariates $\ln\beta$ and $\ln\varepsilon$ in (28) and (29) must be addressed. Indeed, both are unobservable variables that require observable counterparts (proxies) to estimate the models. In the cross-country comparisons, we use two education-level dummy variables, one for highly and another for less-educated couples (mixed-education couples are the reference category) to proxy the productivity level, $\beta$. The idea is simply that, for given training, more educated workers are bound to be more productive than less educated ones. As mentioned earlier, in the Spanish case we will also be able to use a dummy variable of whether the household lives in a region with high productivity (with GDP per capita above the national mean in the 2000-03) as a possibly more reliable proxy for $\ln\beta$, as well as introduce two additional dummy variables capturing the availability of domestic service and family aid. Lastly, individual heterogeneity in the upper bound $\varepsilon$ is captured by children age status (household without children are the reference category).

6.3. Results

OLS results of the common specification (28) used for the three countries are presented in Table 3. Regarding the first set of predictions, our evidence points out that the strongest response of the relative housework share with respect to the female wage takes place in Spain while the weakest impact is found for Norway (indeed the estimated
coefficient in this case is incorrectly signed, yet highly insignificant). This result agrees with the prediction that the coefficient on the female wage should be smaller in economies with lower observed gender gaps, as it is the case of Norway. Moreover, the finding that the estimated coefficients on the wage gap (\(\theta_1\)) are always larger than the one on the female wage (\(\theta_2\)), implies that of the female wage on the female share is negative whereas the effect of the male wage is positive, as predicted by the model. In general, we also find that either a higher education of the spouses or a lower age gap gives rise to a reduction in the female share. Finally, the female share tends to be larger in households with no children, as predicted by our partial equilibrium analysis. As for the second testable implication, we find that the estimated impacts of the different covariates tend to be larger when the extended definition of housework is used.

Note: Heteroskedasticity-robust standard errors. *, **, *** mean significantly different from zero at 10%, 5% and 1% levels, respectively. Age gap is defined as age of the man minus age of the woman. The definition of less- educated couples is that both partners have less than a college degree, while highly- educated couples are those where both partners have a college degree.

---

20 The estimated coefficients in Table 3 can be used to compute the percentage-points change in the female housework share, \(s\), corresponding to a change of \(x\%\) in each of the spouses’ wages. For example, in the case of Spain, using the definition of housework which includes childcare, the coefficient on the male wage is 0.27. Thus, \(\frac{\partial s}{\partial \ln W_f} = [\frac{\partial s}{\partial \ln (s/1-s)}]0.27 = s(1-s)0.27\). Using the average value of \(s\) in Table 1 (0.76) an increase of 10% in the husband’s wage yields a rise of 0.5 percentage points in \(s\). Similar calculations imply that a 10% point increase in the wife’s wage leads to a reduction of 0.38 percentage points in \(s\).
Table 4 provides estimation results for the reduced-form equation (29). Two findings stand out. First, the signs of the coefficients on the variables capturing $\ln \beta$ remain the same as in (28), indicating that $\gamma \in (0,2)$ is the most plausible range of values in the three countries, as we conjectured before. Secondly, and in sharp contrast with the results in Table 3, having children in the household now leads to a rise of the female housework share rather than to a reduction, in line with the different predictions of the model under partial and general equilibrium.

Note: As in Table 3.

Finally, Table 5 presents further results regarding the estimation of (28) for Spain, where the three new indicator variables, only available for this country, have been added to the list of covariates included in Table 3. The first one is a dummy variable that captures residence in a region with high aggregate productivity. Using indexes of regional labour productivity in 2002-03, the indicator takes a value of 1 for couples living in one of the five regions with the highest GDP per employee (Balearic Islands, Cataluña, Madrid, Navarra and the Basque Country) out of the seventeen regions in which Spain is divided. The remaining two dummy variables take a value of 1 for households with domestic help, and for those receiving family-aid subsidies, respectively. Our main finding here is that this extended specification has the same qualitative features of the one reported in Table 3 for this country. Regarding the dummy variables, we find that living in a high productivity region reduces the female
share, as it is also the case of having domestic help. However, there is no evidence on family-aid effects is inconclusive since the coefficient on this dummy is statistically insignificant. One possible reason for this last result is that family-aid in Spain is often means-tested and is hence capturing the fact that the household is low income. Since family-aid would tend to reduce the female share but lower income tends to increase it, the two offsetting effects can cancel out.

N.obs. (couples) 2915 2915

Note: As in Table 3. STUS is the source for the last three dummy variables.

Additional specifications of (28) have been tried without altering the main qualitative results presented above. For example, neither the inclusion of quadratic terms in the partners’ wages (to account for previous evidence on the existence of a convex effect in the impact of relative earnings on the relative housework due to social norms; see, e.g., Bittman et al., 2003) - nor interactions of the education dummies and the age gap with the wages led to statistically significant coefficients on those terms.

6.3. Female share of housework and family-aid policies

The empirical predictions of the proposed model regarding the effects of a subsidy are
not clear-cut: in asymmetric households where men have more bargaining power than women, a subsidy targeted at working women can shift the G-equilibrium to the U one. However, in a symmetric household, the U-equilibrium can only be achieved through a neutral-gender subsidy targeted at both members of the household. As already mentioned, this empirical prediction cannot be tested with the available data since MTUS lacks information on this issue and the STUS does not report whether the husband, wife or both members of the household receive family-aid. Given these shortcoming, all we can report is some very basic descriptive evidence on the correlation between the female share of housework for the MTUS participant countries in Figures 1 to 3 and the percentage of GDP spent on family aid expenditure in those economies.\footnote{It includes cash transfers, services and tax breaks towards family; see \url{www.oecd.org/els/social/family/database}.} Figure 7 shows a very negative correlation between both variables: countries which devote a greater share of the GDP to family aid are those where the female share of housework is lower, and vice versa. This preliminary evidence may be interpreted in terms of our discussion in section 5.3 about asymmetric economies with different bargaining power in the household or in terms of our collective household decision model if targeted aid received by one of the spouses becomes neutral through within-household redistribution exist. However, clearly more research needs to be done in order to clarify the channels through which these subsidies affect household decisions.

7. Conclusions

We have proposed a simple model of self-fulfilling prophecies in which statistical discrimination results in both wage and housework time differences across \textit{ex ante} generically identical individuals, except for gender. In contrast to a large strand of this literature, our model does not rely on either moral hazard due to unobservable effort, efficiency wages in some sectors or adverse selection problems. In our setup, employers would provide identical training to \textit{ex ante} equally-able men and women in the absence of uncertainty. However, under uncertainty, they form different expectations about the burden of household disutility shocks (unexpected need of household work) that each of the spouses would face once they have been trained for their jobs. If they believe that women are more likely to quit than men when shocks occur, they will offer them less training leading to a gender wage gap. Conversely, couples make decisions about the division of household tasks taking future wages as given. If they believe that male wages would be higher, wives would devote relatively more time to housework than husbands would do, validating in this way both sets of beliefs.

The model gives rise to two types of equilibria - gendered and ungendered - leading to several policy implications which are harder to obtain in other models. First, in contrast to most of the literature, welfare in the symmetric equilibrium can be greater than in the asymmetric one. The reason for this result is that having one member of the household specializing in home production has two opposing effects: on the one hand, it leads to larger expected household income, as it is standard in the existing literature; on the other, the disutility of housework is minimized when this task is evenly shared amongst household members. Which effect dominates depends crucially on the level of productivity: the ungendered equilibrium results generally in higher welfare in highly productive economies, while the opposite holds in less productive ones. The immediate implication of this result is that the desirability of policy intervention may not be the same in all economies. In particular, we have shown that a gender-targeted policy (e.g., wage subsidies targeted to married women) may not only fail to achieve a symmetric equilibrium but could also worsen the prior gender wage gap. By contrast, we show that a gender-neutral subsidy (i.e., targeted to both members of the couple) could be more efficient in achieving an ungendered equilibrium, and that such policy works better in more productive economies.

Empirical evidence using micro data from time-use surveys for Spain, Norway
and the UK yields some support to of our main theoretical predictions concerning the relationship between wages and the sharing of household tasks, as well as the role of productivity. However, more empirical work is clearly needed in order to test other implications, notably the effect of alternative tax-subsidy policies whose effects cannot be identified with the datasets at hand. This remains in our future research agenda.

The two housework share variables used in the empirical analysis are:

1) AV7: Housework, which includes the following activities: Washing clothes, hanging washing out to dry, bringing it in, Ironing clothes, Making, changing beds, Making, changing beds, Dusting, hovering, vacuum cleaning, general tidying, Outdoor cleaning, Other manual domestic work, Housework elsewhere unspecified, Putting shopping away.

2) AV7+AV11, where AV11 is childcare, and includes the following activities: Feeding and food preparation for babies and children, Washing, changing babies and children, Putting children and babies to bed or getting them up, Babysitting (i.e. other people’s children), Other care of babies, Medical care of babies and children, Reading to, or playing with babies and children, Helping children with homework, Supervising children, Other care of children, Care of children and babies – unspecified.
Appendix 2: Log-linearization of equation (11)

To log-linearize a function \( f(X) \), with \( X > 0 \), around a reference value, \( \bar{X} \), recall that
\[
f(X) \approx f(\bar{X})[1 + \eta x],
\]
where \( x = \ln X - \ln \bar{X} \) and \( \eta \equiv (\partial f(\bar{X})/\partial \bar{X}) \cdot (\bar{X} / f(\bar{X})) \). Now, write the inverse of (11) as
\[
\left( \frac{s}{1 - s} \right)^2 = \frac{1 - a_f}{1 - a_m}, \tag{A.1}
\]
where \( a_i = W_i^2 / 2 \varepsilon \beta^\gamma, (i = f, m) \). Then, using the previous result, log-linearization of (A.1) around the reference values \((s/1-s)^*\) and \(a_i^*\) yields
\[
\ln \left( \frac{s}{1 - s} \right) = 0.5 \left( \frac{a_m^*}{1 - a_m^*} \ln a_m^* - \ln a_f^* + \frac{a_m^* - a_f^*}{(1 - a_m^*)(1 - a_f^*)} \ln a_f^* \right). \tag{A.2}
\]
Since \( \ln a_i = 2 \ln W_i - \ln 2 - \gamma \ln \beta - \ln \varepsilon \), we get equation (28) in the main text, where
\[
\theta_1 = \frac{a_m^*}{1 - a_m^*} > 0, \quad \theta_2 = \frac{(a_m^* - a_f^*)}{(1 - a_f^*)(1 - a_m^*)} > 0, \quad \theta_3 = -0.5 \gamma \theta_2 < 0, \quad \text{and} \quad \theta_4 = -0.5 \theta_2 < 0.
\]
It can be easily checked that, under Assumption 1, \( \theta_1 > \theta_2 > 0 \). Further, since \( \theta_2 \) is proportional to \( (a_m^* - a_f^*) \), it should be smaller for countries with gender gaps closer to the ungendered equilibrium, in which \( a_m^* = a_f^* \). Note that this is not the case for \( \theta_3 \) and \( \theta_4 \) since \( \gamma \) and the coefficients on the covariates used to proxy \( \ln \beta \) and \( \ln \varepsilon \) could differ in size across countries.
